ABSTRACT

Objective: Although orthoptists play an integral role in the care of patients with chronic eye diseases, the clinical decision making of orthoptists within this setting has not often been investigated. The aim of this study was to evaluate the inter-rater agreement between orthoptists and an ophthalmologist in determining whether anti-VEGF treatment for neovascular (wet) age-related macular degeneration (AMD) is required based on optical coherence tomography (OCT) interpretation.

Methods: A retrospective audit was conducted of patient data from a private ophthalmology practice. Data collected included details pertaining to patient demographics and clinical assessment, OCT retinal thickness, and the treatment decisions of five orthoptists and one senior vitreoretinal ophthalmologist when interpreting OCT scans. The inter-rater agreement between the orthoptists and the ophthalmologist was calculated as a percentage and the kappa (κ) statistic computed.

Results: Of a total 669 treatment decisions made, on 619 occasions (92.5%) agreement was found between the orthoptists and the ophthalmologist (κ = 0.85; 95%CI 3.43 - 1.26, p < 0.001) representing an almost perfect agreement.

Conclusion: Agreement between the orthoptists and ophthalmologist in AMD clinical decision making is very high suggesting that orthoptists could potentially have a greater involvement in shared-care models within specialist eye clinics.

Keywords: neovascular age-related macular degeneration, orthoptist, inter-rater agreement, anti-VEGF clinical decision making, optical coherence tomography

INTRODUCTION

As a consequence of population ageing, it is well known that the demand for eye care services is rapidly increasing. The most prevalent causes of vision impairment in developed countries are those related to ageing: age-related macular degeneration, cataract, glaucoma, diabetic retinopathy and refractive error.1 Age-related macular degeneration (AMD) is the most common cause of irreversible vision loss world-wide and in Australia accounts for 50% of all cases of legal blindness in those aged 40 or older.2

AMD is a progressive eye condition that results in loss of central vision. Treatment options in the most severe form of the disease, neovascular AMD (nAMD), aim to slow disease progression. The current treatment method of choice involves intravitreal injection of an anti-vascular endothelial growth factor (VEGF) drug. Injections are continued indefinitely and usually administered on a needs-only basis dependent on disease activity.2,3 To monitor disease progression, patients with nAMD undergo regular ophthalmic examinations involving an assessment of the fundus, including retinal imaging with optical coherence tomography (OCT). Whilst fundus fluorescein angiography (FFA) is considered the gold-standard for the differential diagnosis of nAMD, OCT imaging is increasingly used as a diagnostic tool prior to angiography4 and performed to determine clinical management. Information obtained from the OCT scan, such as the presence/absence of fluid and change in retinal thickness, greatly influences the re-treatment decision.5,6 A normal appearance on OCT is shown in Figure 1 and presence of fluid with increased retinal thickness is shown in Figure 2.

Whilst ophthalmologists are responsible for the management of patients with nAMD, orthoptists are increasingly involved in supporting patient care through their involvement in the visual assessment and OCT imaging of patients with nAMD. Whilst orthoptists...
commonly undertake OCT imaging, interpretation is not a conventional role undertaken during clinical assessment. Traditionally, the expertise of orthoptists has been in strabismus, oculomotility and binocular function investigation and management. In Australia, this role has evolved significantly to include general ophthalmic care within the secondary and tertiary care settings. For example, more recently orthoptists have become involved in diabetic retinopathy screening and grading, and in glaucoma shared-care schemes.7–10 In relation to nAMD, orthoptists are increasingly involved in making recommendations for anti-VEGF treatment particularly on the basis of the OCT assessment.

To the authors’ knowledge, the rate of agreement between five orthoptists and an ophthalmologist working in a private ophthalmology practice in deciding whether anti-VEGF treatment for nAMD is indicated based on the interpretation of OCT images.

**MATERIALS AND METHODS**

**Participants**

A retrospective clinical audit was conducted at a private ophthalmology clinic in Melbourne, Australia. Data was collected from existing data reserves at the clinical practice during nAMD sessions conducted between the 8th April and 3rd September 2013. Three groups of data were collected: i) patient demographics, ii) clinical assessment details, and iii) the treatment decisions of five orthoptists and one senior vitreoretinal ophthalmologist based on the interpretation of the OCT images (Table 1). Each OCT image was reviewed by one of the five orthoptists and the ophthalmologist. At the time of data collection, the mean years of experience of the orthoptists was 3.61 years (range 1 to 4 years). All orthoptists routinely reviewed nAMD patients and received no additional specific training in OCT interpretation for the purposes of this study. The senior ophthalmologist had over 30 years experience in the investigation and management of posterior segment disorders and as such, their clinical decision making skills/treatment decisions were utilised as the ‘gold standard’ in this study.

**Figure 2.** Macular OCT scan showing areas of hyporeflectivity indicating presence of fluid, with increased retinal thickening and loss of foveal contour.
Results

Participants
A statistical power calculation conducted a priori showed that a minimum sample size of 635 eyes was required to detect a statistically significant result, where the minimum acceptable value of kappa was 0.70 and the ideal kappa to detect was 0.80, with power set at 90% and p ≤ 0.05, two-tailed. A total of 669 eyes were included in this clinical audit. This consisted of 402 individual patients, with 267 patients having nAMD in both eyes.

There were 443 eyes of female patients (66%) and 226 eyes of male patients (34%). Right and left eyes were almost equally represented (RE 50.8%, LE 49.2%). The mean BCVA was 64.5 letters (range 0 to 91; SD ± 17.69) and 63.9 letters (range 0 to 90; SD ± 18.83), in the right and left eyes respectively, approximately equivalent to 6/15 Snellen acuity. The measurements of CRT, maximum retinal thickness and PED for the right and left eyes are shown in Table 2.

Inter-rater agreement between orthoptists and ophthalmologist
Of a total 669 treatment decisions made, there were 619 agreements between the orthoptists and the ophthalmologist. This was equivalent to an agreement rate of 92.5%. Conversely, on 50 occasions, the treatment decision of the orthoptist differed to that of the ophthalmologist. This was equivalent to a disagreement rate of 7.5%. The pattern of agreement and disagreement is shown in Table 3, with an almost equal proportion of disagreement between the decision of injection or no injection. The inter-rater agreement between the orthoptists and the ophthalmologist in making a treatment decision based on OCT interpretation was found to be 2 = 0.85 (95%CI 3.434 - 1.258, p < 0.001), representing an almost perfect agreement.
The 50 disagreements were investigated for possible reason(s) contributing to the difference in treatment decision. The clinical notes of the ophthalmologist (where available) were the first source of information when investigating the reason(s) for disagreement. The OCT scans were also retrieved by the study investigators. In a large proportion of cases where there was disagreement between the orthoptist and ophthalmologist, the patient’s OCT scan showed stability of the disease but the ophthalmologist had indicated that it was safer to inject to prevent disease re-activity/ fluid return with no additional commentary provided. Other reasons included subtle disease activity (slight subretinal fluid or slight macular oedema), or the patient was going on vacation and/or unable to attend a future scheduled visit so it was considered necessary to administer treatment at the present visit. On occasions where the orthoptist had indicated an injection was required but no injection was administered by the ophthalmologist, the main reason for the discrepancy was that the disease state was considered stable by the ophthalmologist and as such, no treatment was administered.

DISCUSSION

OCT imaging is gaining increasing recognition as a valuable tool in the diagnosis and monitoring of disease progression in patients with nAMD. In particular, OCT interpretation forms a critical part of the treatment decision-making process in patients with nAMD. Currently, this task is predominantly performed by the treating ophthalmologist. However, the increasing prevalence of nAMD due to an ageing population is likely to translate into greater demand for eye care services in the future. In Australia, the orthoptic scope of practice has expanded over the past few decades in response to heightened service capacity pressures, with orthoptists assuming greater responsibility in the management of glaucoma patients and becoming increasingly involved in paediatric triaging and diabetic screening.7,9,16 The inter-observer agreement for the grading of nAMD features has found a near perfect agreement. Where there was disagreement, the patients were not placed at sight-threatening risk.

This study has been the first to investigate the agreement rate between orthoptists and an ophthalmologist in making a clinical decision as to whether anti-VEGF treatment for nAMD is indicated based on OCT interpretation and has found a near perfect agreement. Where there was disagreement, the patients were not placed at sight-threatening risk.

Previous studies have likewise reported relatively high inter-observer agreement for the grading of nAMD features on OCT scans.5,11-13 The high inter-rater agreement value in the current study could be partially attributed to the use of highly trained orthoptists. Orthoptists involved in this study were recent graduates from La Trobe University where there is a significant focus on the diagnosis and management of ophthalmic disease as well as ocular motility disorders and were routinely working on a clinic dedicated to AMD patients. Another factor which may have contributed to the high agreement rate observed was the use of spectral-domain OCT. All images acquired in this study were obtained using a Spectralis HRA+OCT machine. OCT device-type can influence clinical interpretation of OCT imaging in the context of nAMD.13,14 Spectral-domain OCT systems have been found to generate a higher degree of inter-rater consensus than time-domain OCT systems when judging scans for the presence of intraretinal and subretinal fluid,13,14 and epiretinal membranes.15 Whilst a limitation of these studies was that they only included a small number of independent graders,5 their findings suggest that the choice of spectral-domain versus time-domain OCT systems can impact clinical decision-making in nAMD.

A healthcare model utilising shared-care management of AMD could address the growing demand for eye care. Introducing orthoptist-led AMD screening and monitoring clinics may produce greater efficiency by reducing waiting times for patients and increasing capacity within specialist clinics.

In summary, this study revealed an almost perfect agreement between orthoptists and an ophthalmologist in making treatment decisions for nAMD patients based on OCT interpretation. These early results, in conjunction with those of other studies, lend support to the expanding role of orthoptists and the development of orthoptist-led clinics for screening/monitoring patients with AMD. With the growing ageing population, increasing the orthoptic scope of practice represents a potential solution to ease the burden of chronic eye diseases on the healthcare system. However, it is important to acknowledge that this retrospective review was confined to only one private ophthalmology clinic and data was collected from a small sample of orthoptists and only one ophthalmologist. The inclusion of only one ophthalmologist limits the capacity to identify if there are differences in management decisions between ophthalmologists. For instance, it is likely that some ophthalmologists may have elected not to inject where the nAMD was stable, when the pro re nata regime is used. Furthermore, the ophthalmologist was not masked to the treatment decision made by the orthoptists. Thus, additional studies conducted across a variety of different hospital and clinical settings that involve a larger number of raters, all of whom are blind to the treatment decision of other raters, are required to confirm these findings.
ACKNOWLEDGEMENTS

The authors would like to thank Eye Surgery Associates for allowing the use of their clinic and clinical data, as well as Dr Leila Karimi for her assistance in statistics. A La Trobe University School of Allied Health Honours Research Support Grant enabled the findings of this research to be presented at the 2013 Orthoptics Australia Annual Scientific Conference in Hobart, Australia.
